

Lithium battery positive electrode side reaction

Overview

Lithium-ion batteries experience complex reactions between the electrodes and the electrolyte under non-standard conditions. Investigating these reactions is crucial for ensuring battery durability and safety. In this study, we focus on side reactions in LIBs during overcharging at elevated temperatures. Lithium-ion batteries (LIBs) have gained popularity as power sources for portable devices and electric vehicles (xEVs) [1,2]. xEVs rely on a series of connected modules made up of LIBs. We used $\text{LiNi}_{0.75}\text{Co}_{0.15}\text{Al}_{0.05}\text{Mg}_{0.05}\text{O}_2$ (NCA-Mg), synthesized through coprecipitation, as the active material for the positive electrode [26,27]. To prepare the positive electrode, we used a series of connected modules made up of LIBs. Fig. S1 shows the initial charge-discharge curves of the cell fabricated in this study, the previously reported cell, and the 500-mA h-class 1. The objective of our study was to quantitatively analyze the reactions occurring in LIBs during normal charge-discharge and overcharging, to improve their durability.
